Abstract
The graphene-like two dimensional (2D) inorganic materials have been shown great interest for a variety of applications. In this work, polymer composite nanofibres containing molybdenum disulphide (MoS₂) nanosheets were obtained by electrospinning. The MoS₂ nanosheets were well dispersed inside the fibres, and the nanofibres maintained the fibre morphology well with the MoS₂ nanosheets embedded. The incorporation of MoS₂ nanosheets changes polymer nanofibre morphology from round to ribbon-like. Moreover, through thermogravimetric (TG) analysis and dynamic mechanical thermal analysis (DMTA) measurements, it was found that the MoS₂ nanosheets as an additive material led to an increase in thermal stability and in the storage modulus. This work comprises an extensive approach to producing a novel 2D inorganic-organic composite structure, which should be applicable for membrane engineering with enhanced thermal and mechanical stability.

Key words: electrospinning, MoS₂ nanosheet, poly(vinyl alcohol), composite, nanofibres.

Introduction
Electrospinning has been demonstrated to be a simple and versatile technique for producing fibres and networks from polymer and composite materials. Such fibres and porous polymer membranes allow wide engineering applications, e.g., tissue engineering, water filtration, and energy and environment-related. In particular, many inorganic materials, such as carbon nanotube and graphene, have been used as nanofillers to improve the performance of fibre composites. Accordingly, it is desired that some new materials with attractive properties be prepared as nanofillers in fibres by electrospinning.

The molybdenum disulphide (MoS₂) nanosheet is an attractive inorganic graphene analogue (IGA) among the various 2D materials. The basic unit of MoS₂ is comprised of two layers of sulfur atoms, forming a sandwich structure, with a layer of molybdenum atoms in the middle. Usually, the bulk MoS₂ material is made of 2D layers stacked together by weak van der Waals interaction, which allows to obtain MoS₂ layers via chemical or mechanical exfoliation of bulk material. The MoS₂ layers exhibit unique properties like optical, luminance, mechanical and electrical, making them attractive for the application of optics, sensors, electronics, catalysts and transistors. The fascinating properties of the MoS₂ layers make it desirable to investigate whether MoS₂ would be good a nanofiller for electrospun nanofibres. Previously, many reports have shown the compatibility of MoS₂ nanosheets with polymers by incorporating them into a variety of polymer matrices. For example, composites of MoS₂ and polyanilines or polythiophene were fabricated to study their electronic properties. Recently, Coleman and other researchers prepared MoS₂ nanosheets by liquid exfoliation and obtained composites with different polymers. It has been suggested that MoS₂ nanosheets could enhance the thermal, mechanical and fire safety properties of the composites. To date, most of the aforementioned researches on MoS₂-polymer composites have been based on dense film composites prepared by the casting process. Fabric nanocomposites containing MoS₂ nanosheets have hardly been reported.

In this work, we successfully prepared 1D poly(vinyl alcohol) (PVA) nanofibres containing 2D MoS₂ nanosheet materials via the electrospinning process. We mainly focused on what effect the 2D MoS₂ nanosheets would have on the nanofibre. PVA was chosen as the electrospun polymer for its biocompatibility, biodegradability and water-solubility. We undertook MoS₂ nanosheet dispersion in water, and then the PVA/MoS₂ composite solution was electrospun into nanofibres. The morphology and structure of the fibres are strongly dependent on the electrospinning parameters and the properties of the spinning solution. The influence of process conditions on the nanofibre morphology were systematically investigated, including PVA concentrations of the spinning solution and the MoS₂ filler concentration, as well as the applied voltage. Moreover, thermal and mechanical properties of the composite fibres were studied.

Experimental
Materials
Molybdenum disulfide (MoS₂) powder and n-butyllithium (n-BuLi) were purchased from Sigma Inc. Polyvinyl alcohol (PVA, 87-89% hydrolysed, M.W = 88,000-97,000) was obtained from Alfa Aesar Inc. The high voltage supply for electrospinning was from Dongwen Inc. (Tianjing, China).

Preparation of MoS₂ nanosheets
MoS₂ nanosheets were prepared by the Li⁺ intercalation and exfoliation process. Typically, 100 mg of dry MoS₂ powder was added into 5 ml of dry hexane in a nitrogen atmosphere. Then 10 ml of n-BuLi was gradually dropped into the mixture at -78 °C. Then the solution was slowly heated to reflux and reacted for 72 h. The intercalated samples were washed with hexane several times to remove any untreated n-BuLi. The intercalated sample was exfoliated by ultrasonication with DI water in a closed vial, during which process profuse gas was released and an opaque suspension of the nanosheets was formed. The suspension was dialysed for 72 h with DI water in a dialysed bag (450 nm).

Nanofibre fabrication by electrospinning
The spinning solution for electrospinning was prepared by dissolving PV A concentrations of the spinning solution. The influence of process conditions on the nanofibre morphology were systematically investigated, including PVA concentrations of the spinning solution and the MoS₂ filler concentration, as well as the applied voltage. Moreover, thermal and mechanical properties of the composite fibres were studied.
with different amounts of MoS$_2$ solution. The solution obtained was transparent with a light brown colour, indicating good dispersion of the MoS$_2$ nanosheets in the PVA solution. For the electrospinning process, the needle of a solution-loaded syringe was connected to a high-voltage supply. The distance between the tip of the needle and the collector was set at 10 cm. The feed rate of the spinning solution was set at 5 mL min$^{-1}$ by a syringe pump. The fibres were collected on an Al foil negative electrode under certain applied potential. The morphology of the fibres could be adjusted by changing various parameters of the fabrication process, such as PVA, MoS$_2$ concentrations and the applied voltage. All the samples prepared at different parameters are listed in Table 1, labelled with ticks. The concentration of PVA and MoS$_2$ represent their weight ratio to the total spinning solution.

**Characterisation**

Transmission electron microscopy (TEM, Tecnai-G2-F30) were performed by directly spinning fibres on a TEM grid. The morphology of the fibres was characterised using a scanning electron microscope (SEM, Hitachi S-4800) and atom force microscopy (AFM, Agilent 5400). X-ray diffraction (XRD, XRD-6000 Bruker) were conducted at an interval of 0.2 degree. Thermogravimetric (TG) analysis was performed at a heating rate of 10°C min$^{-1}$ (1090B TG instrument, DuPont Inc). Dynamic mechanical thermal analysis (DMTA) was performed using a DMTA Q800 (TA, USA). Fibre samples were cut to 5 × 20 mm with a thickness of around 30 μm.

### Results and discussion

**Miromophology of MoS$_2$ nanosheets and PVA/MoS$_2$ fibres**

Typical TEM images of MoS$_2$ nanosheets by the Li$^+$ intercalation and exfoliation process are shown in Figure 1.a. It is obvious that 2D MoS$_2$ nanosheets of several hundred nanometers diameter were obtained. Actually, MoS$_2$ nanosheets with a wide range of diameters were prepared by this process. MoS$_2$ nanosheets obtained by this method are highly crystalised, which can be confirmed by the clear lattice feature of (100) in Figure 1.b. The typical morphology of the fibres produced (14% PVA, 0.025% MoS$_2$, 12 kV) was measured by SEM. It is shown that the PVA/MoS$_2$ fibres have a smooth surface without obvious protuberance on the fibre (Figure 1.c). The average diameter of the nanofibre is around 600 nm. Interestingly, the fibre structure shows ribbon-like morphology, in contrast to the round shape of commonly reported nanofibres. This ribbon-like structure can be clearly observed from the side view of the fibre (Figure 1.d), in which the width is around 1.5 μm, while the thickness is less than 100 nm. In particular, the ribbon-like fibre in Figure 1.d is suspended but not adhered to the substrate, which indicates that this morphology is not directly caused by the substrate effect. The PVA/MoS$_2$ fibre produced was also characterised by TEM measurement (Figure 1.e and 1.f). The MoS$_2$ sheets are apparently embedded inside the PVA fibres. Importantly, with the existence of MoS$_2$ sheets, there is a larger diameter of the composite fibre. The results in Figure 1 imply the important role of MoS$_2$ in the morphology of PVA/MoS$_2$ composite fibres.

**Influence of spinning voltage on the morphology of PVA and PVA/MoS$_2$ fibres**

To check the voltage effect, we firstly produced PVA nanofibres at different voltages: 6, 8, 10 & 12 kV, using 14% PVA solution. For all the applied voltages, there are stable injections for the electrospinning, and smooth fibres are collected on the negative substrate, which means that the electrical repulse force induced by the high voltage can balance the surface tension. The fibre collecting yield at 12 kV is obviously higher than that at 6 kV, due to the high electrical charge on the Taylor cone surface. The nanofibre morphology gradually changed from ribbon-like to a round shape as the electrical potential increased from 6 to 12 kV (Figure 2.a-2.d). In previous reports, Satya Shivkumar et al. obtained a ribbon-like shape of PVA fibres at 30 kV/10 cm by increasing the concentration or molecular weight of the PVA, in which the high

The fibre morphology was further characterized by the tapping mode AFM technique. AFM analysis on silica substrates without destroying the original morphology or size of the fibres suggests that PVA/MoS₂ composite fibres present a ribbon-like shape more than pure PVA fibres, which probably resulted from the surface tension change of the polymer solution. This morphology change also demonstrated the large interaction between the nanosheets and PVA.

**Influence of MoS₂ concentration on the morphology of PVA/MoS₂ fibres**

We also checked the effect of MoS₂ nanosheet concentration on PVA/MoS₂ morphology, in which the PVA concentration was kept at 14%. From the SEM results (Figure 3), it was found that a certain quantity of MoS₂ nanosheets is favorable for yielding a ribbon-like structure. For example, when the MoS₂ concentration is 0.0125% (Figure 3a), the fibres obtained have a round shape similar to pure PVA fibres. While using a 0.025% (Figure 3b) or higher MoS₂ concentration (Figure 3c), the fibre shape presents ribbon-like morphology.

**Influence of PVA concentration on the morphology of PVA/MoS₂ fibres**

For electrospun PVA nanofibres, it is generally concluded that high polymer concentration may result in a ribbon-like structure. Herein, different PVA concentrations were applied to study the morphology of PVA/MoS₂ fibres, where the MoS₂ concentration was kept at 0.025%. For the 8% PVA solution (Figure 4a), we only obtain a round shape of PVA/MoS₂ fibres, even when a low voltage of 8 kV was applied. When a higher concentration of 14 and 16% PVA were used (Figure 4b and 4c), the fibres showed a ribbon-like morphology. Figure 3 and Figure 4 indicate that the concentrations of both PVA and MoS₂ are important to...
PVA/MoS₂ fibre morphology. In our experimental condition, ribbon-like fibres were obtained only when the PVA and MoS₂ concentrations were higher than 14% and 0.025%, respectively.

**AFM analysis**

The fibre morphology was further characterised by the tapping mould AFM technique. Nanofibres from the spinning solution (14% PVA, 0.025% MoS₂) were collected on a clean and hydrophilic silica wafer and dried under a lamp bulb. Before AFM measurement, the silica with fibres was submerged in a crosslink solution (glutaraldehyde in ethanol) for 24 h, and then dried in air. This treatment fixed the fibres tightly to the silica substrate without destroying the original morphology or size of the fibres. It is indicated that the fibres obtained at different voltages possess a remarkable ribbon-like structure (Figure 5). The width is much larger than the thickness of the fibres. Interestingly, the thickness at the two edges is larger than that in the central domain. This phenomenon was also observed with other polymers before. As the voltage increases, the fibres obtained become much narrower and thicker, which is consistent with the results of SEM measurement.

**XRD and TG analysis**

X-ray diffraction (XRD) was used for determining whether MoS₂ nanosheets were indeed present as separated sheets in the nanofibres. In the XRD patterns (Figure 6.a), pure PVA exhibits a broad diffraction peak around 19.51°, resulting from its (101) crystal planes, and the strongest peak (20 = 14.4°) was observed corresponding to the (002) plane of bulk MoS₂ (JCPDF No: 24-0513). After the MoS₂ nanosheets were electrospun into PVA nanofibres, the XRD pattern of the PVA/MoS₂ nanocomposite only showed the diffraction peak of PVA, with no such observation for MoS₂ powder. It can be seen that no bulk MoS₂ exists in the nanofibres and that the MoS₂ nanosheets are separated from each other with no aggregation. Furthermore, TG analysis was used for rapid evaluation of the thermal stability for various polymers (Figure 6.b). Both pristine PVA and PVA/MoS₂ nanofibres decompose in a two-step process. When the first major weight loss occurs at ~330 °C, the decomposition pattern and mass loss (~58%) are nearly the same for the two samples, which can be attributed to the degradation of PVA chains. The second mass loss stage occurs from 360 to 470 °C, and is due to dehydration in the PVA chains. However, the mass loss of the PVA/MoS₂ nanocomposite is slower compared to that of pure PVA at the second stage. The mass loss of the composites is only around 82%, which is obviously lower compared with the mass reduction of 91.5% for pure PVA fibres at 470 °C. The TG analysis results suggest that the existence of MoS₂ nanosheets inside PVA/MoS₂ would retard the thermal degradation of PVA chains, which might be attributed to the limit of the motions of polymer chains through the interactions between MoS₂ nanosheets and PVA.

**DMTA analysis**

To better understand the PVA/MoS₂ interaction, we also performed dynamic mechanical thermal analysis (DMTA) measurements for pure PVA and PVA/MoS₂.
composite nanofibres. In the DMTA test, the storage modulus (E’) is a measurement of the stiffness, which is proportional to the energy stored elastically. The loss modulus (E’”), on the other hand, measures the energy transferred to heat. The temperature at the maximum of tan δ is usually taken as the glass transition temperature (Tg). The storage modulus (E’) is a measure of the stiffness, which is proportional to the energy stored elastically.

Conclusions

We succeeded in synthesising MoS2 nanosheets and producing PVA/MoS2 composite nanofibres by the electrospinning process. In comparison with pure PVA polymer fibres, the PVA/MoS2 fibres obtained tend to form a ribbon-like morphology. The PVA and MoS2 concentration, as well as the spinning voltage applied are important for the formation of ribbon-shaped PVA/MoS2 composite fibres. The higher the concentration of PVA and filled MoS2 and the lower the spinning voltage, the easier the formation of ribbon-shaped PVA/MoS2 composite fibres. Moreover, the incorporation of MoS2 nanosheets can improve the thermal stability and enhance the storage modulus of the composite nanofibres. This work comprises an extensive approach to producing composite nanofibres containing other 2D inorganic materials, such as BN, NbSe2, Co3Se4 and MoSe2.

A cure against excessive fragmentation
Until recently, there were 37 research institutes in Poland, operating under the supervision of ministries. This led to significant issues of scale. The Łukasiewicz Research Network offers a uniform and simple rules of cooperation with businesses, commercialisation of knowledge, development, and use of academic infrastructure. The cooperation instead of destructive competition and fragmented resources.
